

Joint ESPGHAN/NASPGHAN Guidelines for the Management of *Helicobacter pylori* in Children and Adolescents (Update 2016)

*Nicola L. Jones, †Sibylle Koletzko, ‡Karen Goodman, §Patrick Bontems, ||Samy Cadranel, ¶Thomas Casswall, #Steve Czinn, **Benjamin D. Gold, ††Jeannette Guarner, †††Yoram Elitsur, §§Matjaz Homan, ||||Nicolas Kalach, ¶¶Michal Kori, ###Armando Madrazo, ***Francis Megraud, ††††Alexandra Papadopoulou, and †††††Marion Rowland, on behalf of ESPGHAN, NASPGHAN

ABSTRACT

Background: Because of the changing epidemiology of *Helicobacter pylori* infection and low efficacy of currently recommended therapies, an update of the European Society for Paediatric Gastroenterology Hepatology and Nutrition/North American Society for Pediatric Gastroenterology, Hepatology and Nutrition recommendations for the diagnosis and management of *H pylori* infection in children and adolescents is required.

Methods: A systematic review of the literature (time period: 2009–2014) was performed. Representatives of both societies evaluated the quality of evidence using GRADE (Grading of Recommendation Assessment, Development, and Evaluation) to formulate recommendations, which were voted upon and finalized using a Delphi process and face-to-face meeting.

Results: The consensus group recommended that invasive diagnostic testing for *H pylori* be performed only when treatment will be offered if tests are positive. To reach the aim of a 90% eradication rate with initial therapy, antibiotics should be tailored according to susceptibility testing. Therapy should be administered for 14 days, emphasizing strict adherence. Clarithromycin-containing regimens should be restricted to children infected with susceptible strains. When antibiotic susceptibility profiles are not known, high-dose triple therapy with proton pump inhibitor, amoxicillin, and metronidazole for 14 days or bismuth-based quadruple therapy is recommended. Success of therapy should be monitored after 4 to 8 weeks by reliable noninvasive tests.

Conclusions: The primary goal of clinical investigation is to identify the cause of upper gastrointestinal symptoms rather than *H pylori* infection. Therefore, we recommend against a test and treat strategy. Decreasing eradication rates with previously recommended treatments call for changes to first-line therapies and broader availability of culture or molecular-based testing to tailor treatment to the individual child.

Key Words: adolescents, antibiotic susceptibility, ¹³C-urea breath test, children, eradication, *Helicobacter pylori*, triple therapy

Helicobacter pylori infection is acquired in childhood and remains an important cause of peptic ulcer disease (PUD) and gastric cancer (1). In comparison with adults, children and adolescents, however, infrequently develop these complications of infection. Furthermore *H pylori* infection in early childhood may be associated with immunologic benefits later in life (2).

The updated recommendations were extensively discussed in the light of decreasing efficacy of *H pylori* eradication therapy in children and the rising prevalence of antibiotic-resistant strains. Although *H pylori* infection is always associated with microscopic gastric inflammation, the overwhelming majority of *H pylori*-infected children are asymptomatic. Studies in children do not support a role for *H pylori* infection in functional disorders such as recurrent abdominal pain (3). Therefore in children the decision to investigate and treat the infection should be supported by a clear benefit for the individual child.

There is renewed hope in the potential for primary prevention of infection based on the results of a recent vaccine study in Chinese children (4). Optimization of the vaccine strategy is, however, required to ensure long-lasting protection. Furthermore, additional studies demonstrating efficacy in different geographic regions are also needed before this vaccination strategy can be adopted in clinical practice.

The recommended goal for *H pylori* treatment is an eradication rate of at least 90% to avoid further investigations and antibiotic use (5). First-line therapies recommended in previous guidelines have unacceptable treatment failures rates (6). Thus, based on the declining prevalence of the infection in some countries, and the ineffectiveness of previously recommended first-line eradication therapies, European Society for Paediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) and North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) determined that updated

TABLE 1. Guideline recommendations

Synopsis of recommendations

1. We recommend that the primary goal of clinical investigation of gastrointestinal symptoms should be to determine the underlying cause of the symptoms and not solely the presence of *H pylori* infection.
- 2a. We recommend that during endoscopy additional biopsies for RUT and culture should only be taken if treatment is likely to be offered if infection is confirmed.
- 2b. We suggest that if *H pylori* infection is an incidental finding at endoscopy, treatment may be considered after careful discussion of the risks and benefits of *H pylori* treatment with the patient/parents.
- 2c. We recommend against a “test and treat” strategy for *H pylori* infection in children.
3. We recommend that testing for *H pylori* be performed in children with gastric or duodenal ulcers. If *H pylori* infection is identified then treatment should be advised and eradication be confirmed.
4. We recommend against diagnostic testing for *H pylori* infection in children with functional abdominal pain.
- 5a. We recommend against diagnostic testing for *H pylori* infection as part of the initial investigation in children with iron deficiency anemia.
- 5b. We suggest that in children with refractory IDA in which other causes have been ruled out, testing for *H pylori* during upper endoscopy may be considered.
6. We suggest that noninvasive diagnostic testing for *H pylori* infection may be considered when investigating causes of chronic immune thrombocytopenic purpura (ITP).
7. We recommend against diagnostic testing for *H pylori* infection when investigating causes of short stature.
8. We recommend that before testing for *H pylori*, waiting at least 2 weeks after stopping proton pump inhibitor (PPI) and 4 weeks after stopping antibiotics.
- 9a. We recommend that the diagnosis of *H pylori* infection should be based on either (a) histopathology (*H pylori*-positive gastritis) plus at least 1 other positive biopsy-based test or (b) positive culture.
- 9b. We recommend that for the diagnosis of *H pylori* infection at upper gastrointestinal endoscopy, at least 6 gastric biopsies be obtained.
10. We recommend against using antibody-based tests (IgG, IgA) for *H pylori* in serum, whole blood, urine, and saliva in the clinical setting.
11. We recommend that antimicrobial sensitivity be obtained for the infecting *H pylori* strain (s), and eradication therapy tailored accordingly.
12. We recommend that the effectiveness of first-line therapy be evaluated in national/regional centers.
13. We recommend that the physician explain to the patient/family the importance of adherence to the anti-*H pylori* therapy to enhance successful eradication.
14. We recommend first-line therapy for *H pylori* infection as listed in Table 2.
15. We recommend that the outcome of anti-*H pylori* therapy be assessed at least 4 weeks after completion of therapy using one of the following tests.
 - (a) The ¹³C-urea breath (¹³C-UBT) test or (b) a 2-step monoclonal stool antigen test.
16. We recommend that when *H pylori* treatment fails, rescue therapy should be individualized considering antibiotic susceptibility, the age of the child, and available antimicrobial options.

IDA = iron deficiency anemia; RUT = rapid urease test.

guidelines for *H pylori* infection in children and adolescents were required.

These guidelines apply only to pediatric patients, defined as children and adolescents below 18 years of age. Recommendations for children and adolescents may differ from recent guidelines for adults because of a different risk-benefit ratio depending on age and the fact that some antibiotics are not released or licensed for the pediatric population. The guidance in this document does not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual and national circumstances, may be appropriate. This applies particularly to developing countries with high *H pylori* infection rates in children and adolescents and with limited resources for health care.

METHODS

Scope and Purpose

Joint ESPGHAN/NASPGHAN guidelines were developed for the management of *H pylori* infection in children and adolescents in 2009 and published in 2011 (6). Based on new clinical knowledge and

in particular, increasing challenges with eradication therapy, NASPGHAN and ESPGHAN agreed to review the current literature to provide updated guidelines for the management of *H pylori* infection in the pediatric population in North America and Europe.

Literature Review

A systematic literature search using PubMed, MEDLINE, EMBASE, Cochrane Library, and Scopus databases between October 1, 2009 to September 2014 using the following MESH terms (“Adolescent”[Mesh] OR “Child”[Mesh] OR “Infant”[Mesh] OR “Minors”[Mesh] OR “Pediatrics”[Mesh]) AND (“*Helicobacter pylori*”[Mesh] OR “*Helicobacter Infections*”[Mesh])) (K.G.). Studies were restricted to humans and conference abstracts and non-English literature were excluded.

Review, Grading of Evidence, and Consensus Process

The consensus group consisted of an international group of experts including pediatric gastroenterologists, clinical

epidemiologists, pathologists, and microbiologists. Each member of the consensus group provided disclosure of potential conflict of interest for 24 months prior using the societies' conflict of interest Web-based platforms. The consensus group was divided into 4 working groups (who to test, how to test, who to treat, and how to treat). Each working group reviewed the literature for their assigned topic and produced tables that rated the quality of evidence and strength of the recommendations using GRADE (Grading of Recommendation Assessment, Development, and Evaluation) (7). There were 2 levels of recommendations: strong or weak. The quality of evidence for each statement was graded as high, moderate, or low (A, B, and C). For most of the pediatric studies the evidence was low. In the absence of high-level evidence in the pediatric literature, studies in adults were considered and extrapolation performed, when appropriate. The tables and the referenced literature as full papers were made available to all authors on the Web-based guideline platform. The working groups developed initial recommendations based on the evidence. The entire group then voted anonymously on the initial statements using the Web-based platform. Suggestions for changes to the statements were incorporated and the statements were voted upon a second time before the face-to-face meeting.

In May 2015, a one-day, face-to-face meeting was held in Amsterdam. At the meeting, representatives from each of the groups presented the relevant data, the GRADE recommendations were reviewed, and inclusion and wording of the statements finalized. Lastly, the consensus group voted on their level of agreement with each of the statements. A statement was accepted if there was >75% agreement. Per the GRADE system, "we recommend" was employed if the assigned strength of the recommendation was strong while "we suggest" was employed if the strength of the recommendation was weak or conditional.

Manuscript

Each of the working groups provided a summary of the written background evidence for the statements, which was then used to draft the initial manuscript by the co-chairs (N.L.J., S.K.). The manuscript was circulated to the consensus group for revisions and then to the members of ESPGHAN and NASPGHAN before submission for publication.

Funding Sources

ESPGHAN and NASPGHAN were the sole funding sources for the development of the guidelines.

Recommendations

Table 1 provides a synopsis of the new recommendations. Listed below are the individual recommendations, the GRADE rating, voting results, and a discussion of the supporting evidence. Practical practice points are included for each recommendation to aid the physician in management decisions for the individual patient.

Recommendation 1: We recommend that the primary goal of clinical investigation of gastrointestinal symptoms should be to determine the underlying cause of the symptoms and not solely the presence of *H pylori* infection.

GRADE: This statement reflects consensus opinion on the philosophy of care for children rather than

evidence. Therefore, a GRADE rating was not assigned. Agreement: 100%.

Practice Point

1. *In the absence of PUD herein defined as gastric or duodenal ulceration or erosions, eradication of H pylori infection is not expected to result in improvement of symptoms.*

COMMENT:

Since the last guidelines in 2009 (6), no new data support a role for *H pylori* infection as a cause of symptoms in the absence of PUD. In cases of abdominal pain in which an organic cause is considered, a diagnostic upper endoscopy rather than noninvasive testing for *H pylori* should be performed. This recommendation remains unchanged from the previous guidelines.

Recommendation 2a:

We recommend that during endoscopy additional biopsies for rapid urease test (RUT) and culture should only be taken if treatment is likely to be offered if infection is confirmed.

GRADE: As there are no specific studies addressing this statement, no GRADE was assigned. Agreement: 86%.

Recommendation 2b:

We suggest that if *H pylori* infection is an incidental finding at endoscopy, treatment may be considered following careful discussion with the patient/parents.

GRADE: Weak recommendation. Quality of evidence: low. Agreement: 86%.

Practice Points

1. *If during endoscopy antral nodularity without mucosal lesions (gastric or duodenal erosions/ulcer) is visualized, biopsies for RUT and culture to diagnose H pylori infection and guide treatment should only be taken by the endoscopist if treatment is likely to be offered upon confirmation of infection.*
2. *Upon offering anti-H pylori treatment to children without PUD (as outlined in Tables 2–4), physicians should explain that H pylori infection is not likely to be the cause of the symptoms, and therefore H pylori treatment would not be expected to cure their symptoms. Discussion with parents or older children should include the potential risk of developing complications related to infection (PUD, gastric cancer) later in life weighed against the potential risks of treatment (eg, treatment failure, adverse effects of antibiotic use such as diarrhea, cramps, or negative alterations to the gut microbiome).*

COMMENT:

Diagnostic investigation for *H pylori* in children is justified only in cases in which the expected benefits outweigh the costs and risks of testing and subsequent treatment. Based on current evidence, treatment to eliminate *H pylori* infection is not expected to improve symptoms in children, except in cases of PUD (2). Therefore, if peptic lesions are not clinically suspected or identified by endoscopy, invasive diagnostic testing for the sole purpose of detecting *H pylori* infection should not be undertaken.

TABLE 2. Recommended options for first-line therapy for *H pylori* infection

<i>H pylori</i> antimicrobial susceptibility	Suggested treatment
Known	
Susceptible to CLA and to MET	PPI-AMO-CLA 14d with standard dose* (Table 4)
Resistant to CLA, susceptible to MET	PPI-AMO-MET 14d or bismuth-based†
Resistant to MET, susceptible to CLA	PPI-AMO-CLA 14d or bismuth-based†
Resistant to CLA and to MET	PPI-AMO-MET 14d with high dose for amoxicillin (Table 5) or bismuth-based†‡
Unknown	High-dose (Table 5) PPI-AMO-MET 14d or bismuth-based†‡

AMO = amoxicillin; CLA = clarithromycin; MET = metronidazole; PPI = proton pump inhibitor.

*Or sequential therapy for 10d (see recommendation 14).

†In the case of penicillin allergy: if the strain is susceptible to CLA and MET, use standard dose triple therapy with MET in place of AMO; if the strain is resistant to CLA, then use bismuth-based therapy with tetracycline instead of AMO if older than 8 years.

‡Or concomitant therapy (PPI-AMO-MET-CLA) for 14d (see comment on concomitant therapy in recommendation 14).

H pylori-associated gastritis may, however, be an incidental histopathologic finding during upper endoscopy performed for unrelated indications such as the diagnosis of inflammatory bowel disease, or celiac disease, especially in areas with a high prevalence of infection. The finding of *H pylori*-associated gastritis without duodenal or gastric mucosal lesions poses a dilemma for the pediatric gastroenterologist about whether to recommend eradication treatment. *H pylori*-associated gastritis without PUD, rarely gives rise to symptoms or progresses to more serious disease complications during childhood (2). The lower risk of complications in children may be in part explained by a different immune response toward the infection. In comparison with adults, gastric biopsies obtained from children infected with *H pylori* show a decrease in inflammation. In addition, an increase in the number of immunosuppressive T regulatory (Treg) cells along with an anti-inflammatory IL-10 instead of a proinflammatory IL-17 cytokine response is detected (8,9).

In addition, in high-prevalence communities the reinfection rate in young children after successful eradication may be

significant. A study from Bolivia in a high-prevalence, low-income population showed a reinfection rate 1 year after successful therapy of 20% in children younger than 10 years, compared to 8% in older children and adolescents (10). These figures are higher than reinfection rates in adults patients living in high-prevalence countries in Latin America (11% reinfection rate after 1 year) (11) or children and adolescents living in a low-prevalence country like Germany (2.3% per year) (12).

The risk of *H pylori*-associated cancer or mucosa-associated lymphoid tissue-lymphoma during childhood is extremely low in Europe and North America. The risk/benefit ratio may vary in different regions. In areas with a high rate of gastric cancer such as China or Japan, the benefits of treatment to reduce the risk of gastric cancer development may outweigh the risks of treatment (13). In Western countries there is epidemiologic evidence that *H pylori* infection, especially in young children, may be associated with a reduced prevalence of allergic disease (14–18). Higher prevalence of *H pylori* infection may, however, be a surrogate marker for host demographics that could confer protection against autoimmunity and allergy. Therefore, although there is evidence for a causal relationship in mouse models of asthma and inflammation (18), prospective randomized intervention studies in humans are needed to demonstrate a causal relationship. There are currently no good biomarkers to identify the small number of individuals that will go on to develop more severe sequelae of infection later in life. Thus, the decision to treat *H pylori*-associated gastritis in the absence of PUD when found as an incidental finding at upper endoscopy should be carefully discussed with the patient and family taking into consideration the potential risk and benefits of treatment in the individual patient.

Recommendation 2c: We recommend against a “test and treat” strategy for *H pylori* infection in children. GRADE: Strong recommendation. Quality of evidence: low (indirect). Agreement: 100%.

Practice Points

- The goal of clinical investigation is to detect the cause of the child's symptoms. Since current evidence indicates that *H pylori* infection does not cause symptoms in the absence of PUD, performing a noninvasive test to detect infection and treat if the test is positive is not warranted.

TABLE 3. Standard dosing regimen

Drug	Bodyweight range	Morning dose, mg	Evening dose, mg
PPI*	15–24 kg	20	20
	25–34 kg	30	30
	>35 kg	40	40
Amoxicillin	15–24 kg	500	500
	25–34 kg	750	750
	>35 kg	1000	1000
Clarithromycin	15–24 kg	250	250
	25–34 kg	500	250
	>35 kg	500	500
Metronidazole	15–24 kg	250	250
	25–34 kg	500	250†
	>35 kg	500	500
Bismuth‡	<10 years	262 QID	
	>10 years	524 QID	

PPI = proton pump inhibitor.

*The doses of the different proton pump inhibitors are not equivalent. See comment on PPI in recommendation 14.

†If oral suspension of metronidazole is employed, the dose can be divided to be equal every 12 hours.

‡Bismuth in the United States and Canada comes as bismuth subsalicylate.

TABLE 4. High dosing regimen for amoxicillin

Bodyweight range, kg	Morning dose, mg	Evening dose, mg
15–24	750	750
25–34	1000	1000
>35	1500	1500

COMMENT:

Since the last guidelines in 2009, there is no evidence to support a “test and treat” strategy for *H pylori* infection in children. Therefore, this recommendation against noninvasive testing and treating in case of positive results remains unchanged from the previous guidelines.

Recommendation 3: We recommend that testing for *H pylori* be performed in children with gastric or duodenal PUD. If *H pylori* infection is identified then treatment should be administered and eradication confirmed.

GRADE: Strong recommendation. Quality of evidence: high. Agreement: 100%.

Practice Points

- Although *H pylori* infection is only one of several causes of gastric or duodenal erosions/ulceration in children, it is a treatable condition. Eradication of infection prevents ulcer recurrence. If erosions, ulcers, or scarring are visualized during upper endoscopy, biopsies (as outlined in Recommendation 9) should be taken to identify the presence of *H pylori* infection.
- Proton pump inhibitor (PPI) monotherapy may be continued after eradication therapy for another 2 to 4 weeks in patients with PUD.
- Successful *H pylori* eradication is associated with cure of PUD and very low risk of relapse. Therefore monitoring the success of therapy is mandatory in these patients 4 to 6 weeks after stopping antibiotics and at least 2 weeks after stopping PPI therapy. In case of eradication failure,

the patient should receive rescue therapy as outlined in Table 5.

- Intake of acid-suppressive drugs and antibiotics decrease the sensitivity of all biopsy-based tests for *H pylori* (see recommendation 8). Before endoscopy an accurate history for drug intake during the previous 4 weeks should be obtained from the child and caregivers.
- Active bleeding decreases the sensitivity of biopsy-based tests for infection.
- If false-negative results of invasive tests are suspected due to drug intake or active bleeding, noninvasive tests may be helpful to determine whether the ulcer may be related to *H pylori* infection.
- Successful *H pylori* eradication is associated with long-term cure of PUD in children. Therefore monitoring the success of therapy 4 to 6 weeks after stopping therapy and re-treatment in case of failure is mandatory in these patients.

COMMENT:

Although the rates of *H pylori* infection are declining, infection still remains an important cause of PUD (19). Furthermore, eradication of infection is associated with long-term cure of PUD in children.

In the previous joint guidelines, a weak recommendation for testing for *H pylori* infection in the setting of a first-degree relative with gastric cancer was included (6). As there remains no evidence for this recommendation, and the question rarely arises in clinical pediatric gastroenterology practice, it was decided to remove this recommendation from the current guidelines.

Recommendation 4

We recommend against diagnostic testing for *H pylori* infection in children with functional abdominal pain disorders.

GRADE: Strong recommendation. Quality of evidence: high. Agreement: 100%.

Practice Points

- Children with recurrent abdominal pain without any alarm signs or symptoms most likely have functional pain independent of *H pylori* status.

TABLE 5. Rescue therapies in pediatric patients who failed therapy

	Initial antibiotic susceptibility	Past treatment regimen	Rescue treatment
1	Clarithromycin and metronidazole susceptible	Triple therapy using amoxicillin and clarithromycin Triple therapy using amoxicillin and metronidazole	Triple therapy using amoxicillin and metronidazole Triple therapy using amoxicillin and clarithromycin
2	Clarithromycin and metronidazole susceptible	Sequential therapy	Consider performing a second endoscopy and use a tailored treatment for 14d ; or treat like double resistance (Table 2)*
3	Clarithromycin resistant	Triple therapy using metronidazole	Treat like double resistance (Table 2)*
4	Metronidazole resistant	Triple therapy using clarithromycin	Consider performing a second endoscopy and use a tailored treatment for 14 days or treat like double resistance (Table 2)*
5	Primary antimicrobial susceptibility unknown	Triple therapy or sequential therapy	Consider performing a second endoscopy to assess secondary antimicrobial susceptibility; or treat like double resistance (Table 2)*

*In adolescents levofloxacin or tetracycline may be considered.

- Alarm signs include persistent right upper or right lower quadrant pain, dysphagia, odynophagia, persistent vomiting, gastrointestinal blood loss, involuntary weight loss, deceleration of linear growth, delayed puberty, unexplained fever, and a family history of inflammatory bowel disease, celiac disease, or PUD (20).
- A positive noninvasive test may induce anxiety in children with functional pain or their parents with the consequence of referral for upper endoscopy. Therefore, diagnostic testing for the infection should not be undertaken in these children.

COMMENT:

Treatment to eliminate *H pylori* infection is not expected to improve symptoms in children, except in cases of PUD. Therefore, in children fulfilling the Rome criteria for functional abdominal pain diagnostic testing (noninvasive or invasive) for *H pylori* infection should not be undertaken (21–26). In the absence of alarm signs or symptoms, recent updated recommendations from the committee for ROME IV did not identify compelling evidence to support upper endoscopy as part of the diagnostic work up (20), discussed in comments section for recommendations 2a and 2b.

Recommendation 5a

We recommend against diagnostic testing for *H pylori* infection as part of the initial investigation in children with iron deficiency anemia (IDA).

GRADE: Strong recommendation. Quality of evidence: moderate. Agreement: 93%.

Recommendation 5b

We suggest that in children with refractory IDA in which other causes have been ruled out, testing for *H pylori* during upper endoscopy may be considered. GRADE: Weak recommendation. Quality of evidence: low. Agreement: 100%.

Practice Points

1. A diagnosis of IDA is made when both anemia and iron deficiency are present.
2. Children with IDA should be managed according to current guidelines for the treatment of IDA considering the clinical history and age of the child.
3. Noninvasive testing for *H pylori* is not recommended as part of the initial investigation of IDA in children.
4. If upper endoscopy is clinically indicated in the management of IDA refractory to iron therapy, biopsies for the diagnosis of *H pylori* as outlined in recommendation 9 may be considered.
5. If *H pylori* infection is detected in the setting of refractory IDA, eradication therapy for *H pylori* should be combined with iron supplementation.
6. Noninvasive testing for *H pylori* in the case of refractory IDA is not recommended.

COMMENT:

Children are at particular risk of IDA during the first 5 years of life because of their increased iron requirements during periods of rapid growth (27). More than 300 million preschool and school-age children worldwide are anemic due to iron deficiency (28). The risk factors for IDA and *H pylori* are similar with many children having concomitant IDA and *H pylori* infection (29,30). There is, however, no causal relationship between IDA and *H pylori*. Since

the last guidelines a number of methodologically well-conducted studies have examined the relationship between iron deficiency/IDA and *H pylori*, and all conclude that there is no evidence for a causal relationship between IDA and *H pylori* (31–34).

The possibility that IDA may be due to blood loss associated with PUD, or iron scavenging by the bacteria (35) must be considered in children with refractory IDA who have not responded to initial iron supplementation therapy, rapidly relapse or who have other alarm symptoms (34). If there are clinical indications for upper endoscopy it is suggested that biopsies to confirm or rule out the presence of *H pylori* infection may be considered. Since the publication of the previous guidelines there are no studies that specifically examine the relationship between refractory IDA and *H pylori*. One study (36) that examined the effect of *H pylori* eradication on refractory IDA was excluded because it did not meet the inclusion criteria. Thus this recommendation remains unchanged from previous guidelines.

Recommendation 6

We suggest that noninvasive diagnostic testing for *H pylori* infection may be considered when investigating causes of chronic immune thrombocytopenic purpura (ITP).

GRADE: Weak recommendation. Quality of evidence: low. Agreement: 93%.

Practice Points

1. In the patient with chronic ITP (cITP) and thrombocytopenia, noninvasive testing to diagnose the presence of infection should be employed. If the noninvasive test is positive it has to be decided on an individual basis and depending on the platelet count whether an upper endoscopy is needed before eradication therapy.

COMMENT:

cITP (previously idiopathic thrombocytopenic purpura) in childhood is an autoimmune disease with platelet autoantibody formation resulting in platelet destruction and thrombocytopenia (platelet count $<100 \times 10^9/L$) for at least 12 months before presentation. Since the last guidelines 2 small intervention studies reported results of treating *H pylori* infection in the setting of ITP in children (37,38). In both of these studies, an improvement in platelet count occurred in a proportion of patients following *H pylori* eradication. These studies were, however, nonrandomized and included small numbers of patients with a short follow-up time. In a small, randomized controlled trial of 22 children with *H pylori* infection and cITP, increases in platelet counts were detected in more children in the anti-*H pylori* treatment group; however the follow-up period was short (39). Thus based on these limited studies, a weak recommendation for testing and treating for *H pylori* infection in the patient with cITP was included in the guidelines. Additional well-designed interventional studies are, however, required to provide support for this recommendation.

Recommendation 7

We recommend against diagnostic testing for *H pylori* infection when investigating causes of short stature.

GRADE: strong recommendation. Quality of evidence: moderate. Agreement: 79%

COMMENT:

The hypothesis that eliminating *H pylori* infection in children will prevent growth deficits has been investigated in few adequately designed studies. A few new cross-sectional studies add to the literature on associations between *H pylori* infection and anthropometric indicators in children (40–44), with inconsistent results across studies. Epidemiological, observation or case-control studies are not designed to prove causation. Furthermore, both *H pylori* infection and short stature are associated with low socioeconomic status including poor nutrition. The only well-designed intervention study in the current review period was performed in children in the Colombian Andes in a setting of poor hygiene and high prevalence of both malnutrition and chronic infections (45,46). Thus, further research is needed to assess the effect of offering treatment for *H pylori* in children with short stature in a North American or European setting.

Recommendation 8

We recommend that before testing for *H pylori*, wait at least 2 weeks after stopping PPIs and 4 weeks after stopping antibiotics.

GRADE: Strong recommendation. Quality of evidence: low. Agreement: 100%.

Practice Points

1. Parents and guardians should be asked about drug intake during the 4 weeks before testing.
2. These time intervals apply for primary testing to diagnose or exclude *H pylori* infection and to monitor treatment success. It applies for both invasive and noninvasive (urea breath test [UBT], stool antigen) testing.
3. If acid suppressive therapy cannot be discontinued for 2 weeks because of recurrence of symptoms, changing to an H₂-receptor antagonist with discontinuation of the drug 2 days before testing may improve the sensitivity of the diagnostic test.
4. Antibiotics may suppress bacterial growth and may result in false-negative test results in all applied diagnostic methods except serology (which is not recommended).

COMMENT:

PPI therapy may give false-negative diagnostic test results for *H pylori* infection due to suppression of *H pylori* replication (47). No additional studies have been published since the last guidelines; thus, these recommendations remain the same as the previous guidelines.

Recommendation 9a

We recommend that the diagnosis of *H pylori* infection should be based on either: positive culture or *H pylori* gastritis on histopathology with at least 1 other positive biopsy-based test.

GRADE: Strong recommendation. Quality of evidence: high. Agreement: 100%.

Recommendation 9b

We recommend that at least 6 gastric biopsies should be obtained for the diagnosis of *H pylori* infection during upper endoscopy.

GRADE: Strong recommendation. Quality of evidence: low. Agreement: 93%.

Practice Points

1. It is recommended that the initial diagnosis of *H pylori* infection be performed using invasive gastric biopsy-based methods including the following:
 - a. Positive bacterial culture OR
 - b. *H pylori* gastritis on histopathology using the updated Sydney classification with at least 1 other positive test such as RUT, or molecular-based assays where available, including polymerase chain reaction (PCR), or fluorescent *in situ* hybridization.
2. The initial diagnosis of *H pylori* infection should not be based on noninvasive tests (ie, ¹³C-UBT, *H pylori* stool antigen test) or other noninvasive methods. A positive noninvasive test, however, supports the diagnosis in cases in which positive histology is the only invasive test available.
3. At least 6 gastric biopsies should be taken for the initial diagnosis of *H pylori* infection. Two biopsies should be obtained from the antrum and 2 biopsies from the corpus for the histopathological evaluation applying the updated Sydney classification (48), at least 1 biopsy from the antrum and 1 from the corpus for culture (if available) and at least 1 biopsy for any additional diagnostic tests from the antrum (rapid-urease, or molecular-based assays).
4. In the course of upper gastrointestinal bleeding, false-negative results of gastric biopsy-based methods can occur; that is, histopathology, culture, or RUT. Molecular diagnostic methods may have better test accuracy in this setting (49,50).
5. The transport of biopsies in special transport media rather than normal saline is highly recommended to enhance the success rate for culture.

COMMENT:

These recommendations remain unchanged from previous guidelines. The current reference “criterion standard” for investigating *H pylori*-associated disease in children remains upper gastrointestinal endoscopy with biopsies for culture, histology, and RUT (51). None of the available diagnostic tests have 100% accuracy. Bacterial culture is, however, 100% specific. The positive predictive value of a diagnostic test rapidly decreases if the prevalence of the infection in the population is low, which is the situation in children in most European and North American countries. Therefore, we recommend that the diagnosis of *H pylori* infection be based on 2 tests and not only on a positive histology. During the current review period, Seo et al (52) reported the rate of RUT positivity in 255 *H pylori*-infected children. The authors found that the sensitivity of RUT increased with age (being lowest in the 0–4-year age group) and with the number of biopsies, whereas the time of an RUT to turn positive took longer in the younger age group. The authors explain their findings by a lower bacterial density in children compared to adolescents and adults. Similar to previous findings, a recent study reported that antral nodularity remains a useful diagnostic predictor of *H pylori* gastritis in children (53).

Recommendation 10

We recommend against antibody-based tests (immunoglobulin G [IgG], IgA) for *H pylori* in serum, whole blood, urine, and saliva in the clinical setting.

GRADE: Strong recommendation. Quality of evidence: high. Agreement: 86%.

Practice Points

1. *These antibody-based tests should not be used to detect the presence of active H pylori infection or for use in post-treatment evaluation in children or adolescents.*

COMMENT:

These recommendations remain unchanged from previous guidelines.

Recommendation 11

We recommend that antimicrobial susceptibility be obtained for the infecting *H pylori* strain(s) and, the eradication treatment tailored accordingly.

GRADE: Strong recommendation. Quality of evidence: low. Agreement: 86%.

Practice Points

1. *H pylori antimicrobial susceptibility testing should be based on culture biopsy-based methods (E-test or agar dilution) or molecular biopsy-based techniques (real-time PCR, fluorescent in situ hybridization).*
2. *The transport of biopsies in special transport media will enhance the success rate for culture.*
3. *Molecular methods, especially commercially available kits based on real-time PCR, are suitable to detect H pylori and clarithromycin resistance in gastric biopsy specimens or gastric juice. At this stage these techniques cannot be recommended for detection of antibiotic resistance in stool.*
4. *To increase the sensitivity for detecting antimicrobial resistance of H. pylori strains in children colonized with different resistance patterns it is recommended that gastric biopsies for culture- and molecular-based tests be obtained from at least 2 different locations (ie, antrum and body). The biopsies can be sent to the laboratory in the same jar.*

COMMENT:

Antimicrobial resistance patterns vary depending on national/geographic regions and are a major factor in determining the success of eradication therapy (54–61). Treatment failure will result in increased healthcare utilization, and likely puts the child through additional unnecessary procedures and therapies, and the associated risks. Moreover, eradication failure increases the risk of antibiotic resistance of the infecting *H pylori* strains, thereby reducing the likelihood of successful eradication (55,56). Development of antibiotic resistance may also occur if children are on long-term antibiotics for other comorbidities.

In many countries primary clarithromycin resistance has increased to levels above the recommended threshold (15%) for use as a first-line agent for *H pylori* infection (54). Furthermore, antibiotic resistance rates of *H pylori* can vary among different regions within the same country (58). Thus, national/regional antibiotic resistance data could be used to guide treatment regimens for *H pylori* infection (54). In fact, increasing antimicrobial resistance likely explains the reduction in efficacy of clarithromycin containing regimens over time. Resistance to metronidazole has

also increased in some populations and regions (55,60). In addition, multiple strains with different antibiotic resistance profiles can exist within the same individual (62). In adults, treatment tailored to antimicrobial susceptibility reduces the risk of treatment failure compared with empirical triple therapy (63). Few comparative data including only a small number of children exist in the pediatric literature.

Recommendation 12

We recommend that the effectiveness of first-line therapy be evaluated in national/regional centers.

GRADE: Strong recommendation. Quality of evidence: low. Agreement: 100%.

Practice Points

1. *As antimicrobial susceptibility testing is not available in all centers, we propose that national/regional effectiveness of H pylori eradication regimens in children and adolescents be evaluated if possible.*

COMMENT:

Treatment failure of *H pylori* eradication regimens in routine practice is often associated with inappropriate choice of treatment regimen, poor adherence, and antimicrobial resistance. To avoid further investigations, and induction of secondary resistance in the infecting *H pylori* strains, a primary success rate for eradication should be more than 90% in per-protocol analysis (54). This goal is not achieved in most current published treatment trials in children (63–68). Therefore, benchmarking is a necessity to assess the local performance of the prescribed regimens and to minimize the risk of treatment failure. This is of particular importance in areas in which antimicrobial susceptibility testing is not available.

Recommendation 13

We recommend that the physician explain to the family the importance of adherence to the anti-*H pylori* therapy to enhance successful eradication.

GRADE: Strong recommendation. Quality of evidence: moderate. Agreement: 86%.

Practice Points

1. *Patient information leaflets with individualized schedules for drug intake may improve adherence.*

COMMENT:

Lack of adherence is a significant risk factor for failure of therapy (6). A recent study published outside of the review period demonstrated that a high success rate for eradication therapy was achieved only in the subset of infected children who took at least 90% of the prescribed eradication therapy (67). Recommended eradication protocols are composed of at least 3 drugs given for 10 to 14 days. In addition, therapy-related adverse effects, although mostly minor, are quite frequent. Therefore, a proper and detailed explanation of the recommended therapy, potential side effects, and importance of adherence to parents and children is critical to the success of eradication therapy.

Recommendation 14

We recommend the following as first-line therapy for *H pylori* infection as outlined in Table 2.

GRADE: Strong. Quality of evidence: moderate to low for suggested regimens; low for duration; Agreement: 100%.

Practice Points

1. If the strain is susceptible to clarithromycin (CLA) and to metronidazole (MET), triple therapy (PPI, amoxicillin [AMO], CLA) for 14 days is the preferred choice. In comparison with sequential therapy, this regimen will not induce resistance to metronidazole. In case of treatment failure with PPI, AMO, and CLA a switch to PPI, AMO, and MET can be made without further susceptibility testing.
2. Sequential therapy for 10 days (PPI with AMO for 5 days followed by PPI with CLA and MET for 5 days with doses given in Table 3) is equally effective in patients infected with fully susceptible strains. It, however, has the disadvantage of exposing the child to 3 different antibiotics. Sequential therapy should not be given if the strain is resistant to MET or CLA, or if susceptibility testing is not available. The most recent adult guidelines recommend against the use of sequential therapy as first- or second-line therapy (69,70).
3. Doses of PPI and antibiotics should be calculated based on the bodyweight as shown in Table 3.
4. A higher degree of acid suppression improves the success rate of amoxicillin- and clarithromycin-based therapy. Younger children need a higher PPI dose per kg bodyweight compared to adolescents and adults to obtain sufficient acid suppression.
5. Esomeprazole and rabeprazole are less susceptible to degradation by rapid metabolizers with CYP2C19 genetic polymorphism, and therefore, may be preferred when available. Rapid metabolizers are more frequent in the Caucasian population (56%–81%) compared to Asians.
6. The PPI dose given in the table refers to esomeprazole and omeprazole and should be adapted if other PPIs are used. PPIs should be preferentially given at least 15 minutes before meal.
7. For children younger than 8 years, bismuth quadruple therapy refers to bismuth, PPI, AMO, and MET. In children older than 8 years, bismuth quadruple therapy refers to bismuth, PPI, MET, and tetracycline.
8. The routine addition of either single or combination probiotics to eradication therapy to reduce side effects and/or improve eradication rates is not supported by current evidence.

COMMENT:

Treatment success is negatively affected if the strain is resistant to one of the antibiotics used. Thus recommended therapies should be based on knowledge of antibiotic susceptibility testing (Fig. 1). If primary culture and susceptibility testing is not available, then clarithromycin-based triple therapy should not be used as part of first-line therapy due to high rates of clarithromycin resistance rates worldwide (55–61).

The previous optimism for the use of 10-day sequential therapy (PPI with AMO for 5 days followed by PPI with CLA and MET for 5 days) in treatment naïve patients has now been questioned by additional studies in both children (64–66) and adults (68). A meta-analysis of pediatric studies concluded that a 10-day sequential therapy was superior to 7-day standard triple therapy (relative risk 1.17, 95% confidence interval: 1.071,28), but

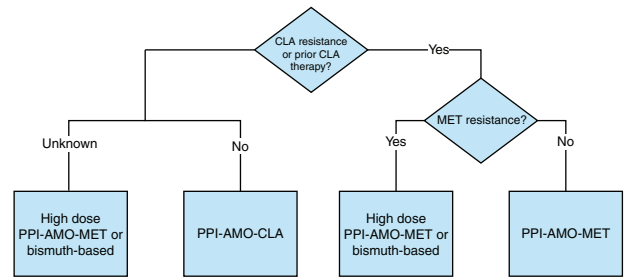

FIGURE 1. Algorithm for selection of eradication therapy for *H pylori* infection in children based on knowledge of antibiotic susceptibility. PPI = proton pump inhibitor.

performed similar to 10- or 14-day triple therapy (65). In an open label, prospective multicenter European study of 165 children, eradication rates with sequential therapy were only 56% when clarithromycin resistance was present (64). Thus, current evidence indicates that sequential therapy should not be recommended in treatment-naïve children when antibiotic susceptibility of the infecting strain is not known. A recently published European pediatric study (67) that was outside the time frame of our review and not included in our analysis, lends support to the recommendation above. In the present study, primary eradication rates with a high-dose sequential 10-day regimen in children with strains susceptible to both clarithromycin and metronidazole were 85.8% in the intention to treat analysis. In the presence of metronidazole or clarithromycin resistance these rates, however, dropped to 73.3% and 71.1%, respectively. In addition to antibiotic resistance, the other major factor affecting eradication in the present study was drug intake of <90% of the prescribed medication dose. Although there are no specific pediatric studies addressing this therapy, a 14-day tailored triple therapy is recommended when *H pylori* stains are resistant to 1 antimicrobial agent (eg, clarithromycin or metronidazole).

There are no new well-designed pediatric studies regarding the use of bismuth in eradication protocols since the last guidelines. One retrospective study in Korean children compared eradication rates with bismuth-based quadruple therapy including omeprazole, amoxicillin, and metronidazole for 7 days with standard triple therapy consisting of omeprazole, amoxicillin, and clarithromycin for 14 days (71). Bismuth-based quadruple therapies had higher eradication rates than standard triple therapy, particularly in the more recent era of 2010 to 2012. Recent meta-analyses in adult subjects indicate that bismuth-based therapy is effective (68). Thus, based on previous literature and adult studies we recommend bismuth quadruple therapy (where available) in children if *H pylori* antimicrobial susceptibility is unknown or in the setting of dual resistance to clarithromycin and metronidazole. The other recommended therapy in this setting is high-dose amoxicillin triple therapy with metronidazole (Table 4). The evidence supporting this regimen is, however, limited. In 1 small open multicenter European study of children infected with clarithromycin- and metronidazole-resistant strains, eradication rates using high-dose amoxicillin and PPI with metronidazole was 66% in intention to treat analysis (72).

In adult patients, a recent meta-analysis showed that concomitant quadruple therapy (PPI and amoxicillin, metronidazole, and clarithromycin given for 10 to 14 days) was one of the most effective treatments, with a high eradication rate and acceptable frequency of adverse events (73). The most recent adult international practice guidelines recommend concomitant therapy as a first-line option (69,70). Currently no studies assessing concomitant

therapy in the pediatric setting are available for comparison. Future studies should assess this therapy in children and adolescents. In children with primary double resistance to clarithromycin and metronidazole, concomitant therapy may be a better option compared to triple therapy with high-dose amoxicillin.

There are limited well-designed studies in children and adolescents with respect to the optimal duration of anti-*H pylori* therapy. Regardless of the length of therapy, the choice of antibiotics or the dosing schedule, eradication rates for most anti-*H pylori* therapies are less than the recommended 90% per protocol treatment success. Meta-analyses of optimal duration of *H pylori* eradication therapy in adults have been performed and show that increasing the duration of therapy enhances eradication rates (74). With respect to triple therapy, a recent systematic review and network analysis of studies in adults showed that 14-day duration of treatment improves eradication rates compared to 10-day, and both are superior to 7-day treatment (68). Of note, longer duration therapies were associated with increased rate of adverse events in the present study.

The role of supplemental probiotic therapy to reduce adverse effects, improve adherence, and, thereby, increase efficacy of *H pylori* eradication regimens remains controversial. Several meta-analyses have attempted to address this (75–77). Although these studies suggest that there may be a benefit for reduction of adverse effects and improved efficacy when added to *H pylori* eradication therapy, the studies included in these meta-analyses employ different probiotic strains and concentrations making it difficult to draw meaningful conclusions. Therefore, additional sufficiently powered pediatric studies with specific probiotic strains should be performed to develop more reliable conclusions about the benefit of probiotics in *H pylori* eradication regimens.

There is no evidence to suggest that testing and treating family members for *H pylori* infection reduces the risk of reinfection. Of note, recent vaccine trials suggest that in areas with high endemic rates of infection, infection rates are low in children older than 6 years (4).

Recommendation 15a

We recommend that the outcome of anti-*H pylori* therapy be assessed at least 4 weeks after completion of therapy.

GRADE: strong recommendation. Quality of evidence: moderate. Agreement: 100%.

Recommendation 15b

We recommend that one of the following tests be used to determine whether *H pylori* treatment was successful:

(1) The ¹³C-UBT.

(2) A 2-step monoclonal stool *H pylori* antigen test.

GRADE: Strong recommendation. Quality of evidence: high. Agreement: 93%.

Practice Points

1. The relief of symptoms is not an indicator for successful treatment. Therefore, all children treated for *H pylori* should be assessed for treatment success with a reliable test.
2. Endoscopy and biopsy-based tests to confirm eradication are rarely needed in pediatric patients with uncomplicated PUD. Gastric and duodenal peptic ulcers have a low risk for relapse with clearance of the infection.

3. The ¹³C-UBT may give false-positive results in children younger than 6 years of age because of the lower distribution volume and different CO₂ production rate (78–80). False-positive results may also be due to technical difficulties in performing ¹³C-UBT in young children because they are often unwilling to swallow the substrate and oral urease-producing organisms can then split the substrate. This has little relevance in clinical practice in which eradication therapy is, however, rarely indicated in children younger than 6 years.
4. The use of ¹⁴C-UBT is not recommended in children.
5. The accuracy of the 2-step monoclonal stool antigen test is comparable to the ¹³C-UBT and performance is unrelated to age. This test is not available (licensed) in North America.
6. The polyclonal stool antigen test has a lower accuracy compared to the ¹³C-UBT and the monoclonal stool test, but may be an option in situations when neither of the other 2 tests are available (81,82).
7. Rapid office-based stool tests have a lower performance compared to laboratory-based tests.

COMMENT:

When considering a test for cure, it is important to employ the most accurate test for active infection (78). In most clinical settings, noninvasive testing, either ¹³C-UBT or fecal antigen testing should be employed to ensure cure of infection has been achieved (78). The ¹³C-UBT is well validated against invasive tests and performs well even with a variety of test protocols (79,80). In contrast, fecal tests depend on the antigen used and may differ in their performance (81–86). For both ¹³C-UBT and fecal antigen testing, false-negative results can occur when medications are taken that decrease the bacterial load or suppress gastric acid (78). Therefore testing for cure should be performed at least 4 weeks after completion of eradication therapy to avoid false-negative results.

Recommendation 16

We recommend that when *H pylori* treatment fails, rescue therapy should be individualized considering antibiotic susceptibility, the age of the child, and available antimicrobial options.

GRADE: Strong recommendation. Quality of evidence: low. Agreement: 93%.

Practice Points

1. See Table 5 for specific recommendations for rescue therapy.

COMMENT:

In comparison with adults, reduced options for rescue therapy exist in children, further emphasizing the need for the selection of initial regimens with the best chance of success. In patients who have previously failed *H pylori* eradication therapy, the choice of rescue therapy should consider initial antibiotic susceptibility status (if known) and the first-line regimens employed (Table 5). Where possible, rescue therapy should be based on antibiotic resistance profiles. Antibiotics with a high likelihood of the infecting strain to develop secondary resistance (eg, clarithromycin, metronidazole) should be avoided if they were employed in the initial regimen. Studies in adults suggest that increasing acid suppression and metronidazole dose may improve

efficacy of eradication therapy (87). Although there are no data addressing this issue for rescue therapy in children, employing higher dosages of PPI and metronidazole may be considered. As described in recommendation 14, 1 study showed that in children infected with clarithromycin- and metronidazole-resistant strains, the eradication rate using high dose amoxicillin and PPI with metronidazole was 66% in intention to treat analysis (72). In a recent multicenter, open-label, single-arm, clinical trial (82) of *H pylori*-positive adults who had failed more than one previous course of omeprazole-amoxicillin-clarithromycin therapy, a quadruple regimen of bismuth, metronidazole, and tetracycline plus omeprazole produced a high eradication rate (up to 95.8%). As expected, these authors concluded that bismuth-based regimen offers an effective option as rescue therapy (88).

SUMMARY

Because of the unacceptably low *H pylori* eradication rates in children reported in the literature from different countries, and the increasing rates of antibiotic resistance, these guidelines now focus on prescribing treatment for *H pylori* in children only when it is clinically indicated, or when following discussion with parents it is deemed appropriate to treat an incidental finding of *H pylori* in children (Table 6). Previous guideline recommendations of triple or sequential therapy for treatment-naïve *H pylori*-infected children and adolescents can no longer be supported. Instead, to achieve an initial eradication success rate of 90% and higher, therapy should be based on knowledge of antibiotic resistance profiles and therapy tailored accordingly using sufficiently high doses and treatment

durations of 10 to 14 days. The importance of adherence for optimal successful eradication should be emphasized to the parents and child. Clarithromycin-containing regimens should be restricted to those infected with clarithromycin-susceptible strains. When antibiotic susceptibility profiles are not known, high-dose triple therapy with PPI, amoxicillin, and metronidazole for 14 days is recommended as first-line therapy. Bismuth-based quadruple therapy can also be considered for first-line therapy in countries where it is licensed for use in children. As with the previous guidelines, testing for cure should be performed with either the C^{13} -UBT or a fecal antigen test at least 4 weeks after therapy to avoid false-negative results. Second-line therapies present a real challenge in children due to the limited number of antibiotics that are appropriate to use in children. Second-line therapies should take into consideration the antibiotics employed for the initial therapy, duration of treatment, and, where possible, should be based on antibiotic resistance profiles.

Future Directions for the Management of *H pylori*-infected Children

Future studies should focus on obtaining antibiotic resistance rates across regions to help direct optimal therapy. In addition, high-quality studies evaluating novel approaches and therapies in children including quadruple concomitant therapy (PPI and amoxicillin, metronidazole, and clarithromycin given for 10–14 days), bismuth-based regimens, and the role of supplemental probiotics are needed. Importantly, studies of prevention of infection with optimization of vaccine strategies should be performed.

TABLE 6. Highlights of changes in new guidelines in comparison to the previous guidelines

New recommendations	Previous recommendations
1. Who to test for <i>H pylori</i> infection	
Testing for <i>H pylori</i> during endoscopy should only be performed if intending to treat	Not addressed
Testing for <i>H pylori</i> is not recommended in the initial investigation of iron deficiency anemia	Not addressed
Weak recommendation to consider noninvasive testing for <i>H pylori</i> infection in the setting of chronic ITP	Insufficient evidence that infection is causally related to ITP
Recommend against testing in the setting of short stature	Insufficient evidence that infection is causally related to short stature
Removal of recommendation for testing in the setting of family history of gastric cancer or MALT, as rarely encountered	Consider testing in the setting of family history of gastric cancer or MALT
2. How to test for <i>H pylori</i>	
Six gastric biopsies for either (a) histopathology (<i>H pylori</i> -positive gastritis) plus at least 1 other positive biopsy-based test or (b) positive culture.	Biopsies from corpus and antrum for histopathology plus rapid urease test or culture
3. Who to treat with <i>H pylori</i> infection	
If <i>H pylori</i> is an incidental finding at endoscopy treatment may be considered following careful discussion of the risks and benefits of <i>H pylori</i> treatment with the patient/parents	When <i>H pylori</i> is detected by biopsy-based methods in absence of PUD, treatment may be considered
Weak recommendation for patient with chronic ITP	
4. How to treat infected patients	
Evaluation of effectiveness of first-line therapy in national/regional centers	Surveillance of antibiotic resistance rates in different countries
Differences in first-line recommended therapies and dosing (see Table 2 and algorithm)	First-line therapy options: standard triple, bismuth + amoxicillin + imidazole or sequential
Tailored treatment based on antibiotic sensitivity where available.	In areas with high clarithromycin resistance, perform susceptibility testing for clarithromycin to tailor its use
Duration of therapy 14 days	Duration of therapy 7–14 days
Higher dose of PPI, particularly in younger children, with doses from 1.5 to 2.5 mg/kg bodyweight and day	PPI dose ranging from 1 to 2 mg/kg bodyweight and day
Recommendation that physician explain to the patient/ family the importance of adherence	Not a specific recommendation, addressed in discussion

ITP = immune thrombocytopenic purpura; MALT = mucosa-associated lymphoid tissue; PPI = proton pump inhibitor; PUD = peptic ulcer disease.

ESPGHAN and NASPGHAN are not responsible for the practices of health care providers and provide guidelines and position papers as indicators of best practice only. Diagnosis and treatment are at the discretion of physicians.
